RESEARCH REPORT

Single-cell resolution of morphological changes in hemogenic endothelium

Frank L. Bos¹, John S. Hawkins¹ and Ann C. Zovein¹,²,*

ABSTRACT

Endothelial-to-hematopoietic transition (EHT) occurs within a population of hemogenic endothelial cells during embryogenesis, and leads to the formation of the adult hematopoietic system. Currently, the prospective identification of specific endothelial cells that will undergo EHT, and the cellular events enabling this transition, are not known. We set out to define precisely the morphological events of EHT, and to correlate cellular morphology with the expression of the transcription factors RUNX1 and SOX17. A novel strategy was developed to allow for correlation of immunofluorescence data with the ultrastructural resolution of scanning electron microscopy. The approach can identify single endothelial cells undergoing EHT, as identified by the ratio of RUNX1 to SOX17 immunofluorescence levels, and the morphological changes associated with the transition. Furthermore, this work details a new technical resource that is widely applicable for correlative analyses of single cells in their native tissue environments.

INTRODUCTION

Endothelial-to-hematopoietic transition (EHT) during embryogenesis provides the first long-term hematopoietic stem and progenitor cells (HSPC) for the organism. Fate-tracing (Zovein et al., 2008), live-imaging (Bertrand et al., 2010; Boisset et al., 2010; Eilkén et al., 2009) and loss-of-function studies (Chen et al., 2009) have demonstrated that a subset of endothelial cells, termed hemogenic endothelium, is capable of generating HSPCs, which first appear as cell clusters of rounded cells attached to the endothelium (North et al., 1999). The best-studied site for HSPC emergence is the developing aorta located in the embryonic aortic-endothelium (North et al., 1999). The relative expression of these two transcription factors (RUNX1 and SOX17) during EHT has not been extensively studied. Here, we present the first report of RUNX1 and SOX17 correlation microscopy analysis in human and murine hemogenic endothelium. The findings illustrate the initiation of EHT on a single-cell level.

RESULTS & DISCUSSION

RUNX1 and SOX17 mark human hemogenic endothelium

We first set out to determine the expression patterns of SOX17 and RUNX1 during human embryonic development. We evaluated the human AGM from 6-8 weeks gestational/menstrual age (GA), which corresponds to developmental stages of 4-6 weeks (Fig. 1; supplementary material Fig. S1). Endothelial cells are identified by PECAM-1 and VE-cadherin (CDH5, referred to here as VEC), whereas CD143 (angiotensin-converting enzyme, ACE) has been shown to identify human AGM endothelium and associated cell clusters (Jokubaitis et al., 2008) (Fig. 1A-E; supplementary material Fig. S1A,B). In addition, as Runx1 has been demonstrated to be crucial to EHT in the murine system (Chen et al., 2009), we evaluated RUNX1 in human hemogenic endothelial cells and hematopoietic cluster cells (Fig. 1B-G). RUNX1 in the human system is noted within intra-aortic clusters (Fig. 1B,C) but is also present in a small subset of single endothelial cells within the aorta (Fig. 1D-G; supplementary material Fig. S1C,D). The localization of SOX17 to arterial endothelium is also observed in another known hemogenic site, the vitelline artery (de Bruijn et al., 2000) (supplementary material Fig. S1E,F). The single endothelial cells within the aorta that exhibit high RUNX1 immunofluorescence also display lower levels of SOX17 immunofluorescence (Fig. 1F,G, arrowheads). As SOX17 and RUNX1 appear to have opposing expression domains, we quantified the levels of RUNX1 and SOX17 per individual aortic endothelial cell, and determined the ratio of RUNX1/SOX17 via mean fluorescence intensities (MFI) of three-dimensional (3D)-rendered nuclear volumes (Fig. 1H-J). Cells with a low ratio (<0.1) are considered mostly endothelial, with near-undetectable levels of RUNX1. High RUNX1/SOX17 ratios (>1) suggest either a hemogenic endothelial cell in transition or hematopoietic cell fate change. Our analysis also reveals endothelial cells that exhibit intermediate ratios, which might represent the early stages of EHT (Fig. 1J). Taken together, during human development, RUNX1 – and, separately, SOX17 – demonstrate high expression in distinct and separate cell populations within the aorta, such that the ratio of RUNX1/SOX17 may predict stages of EHT.
Single-cell analysis of murine hemogenic endothelium reveals hematopoietic transition

In order to study the developmental stages that span hematopoietic emergence, we expanded our evaluation to the murine system. We first investigated hemogenic endothelial sites prior to the appearance of intra-aortic clusters (~E9.5). Endothelial cells exhibited immunofluorescence for VE-cadherin, SOX17 and RUNX1 (Fig. 2; supplementary material Fig. S2A-E). Immunofluorescence levels of RUNX1 and SOX17 with corresponding ratios per individual cell were quantified (Fig. 2A-G). We noted a large range of calculated ratios, possibly representing different stages of EHT (Fig. 2D,F,G). Cells with relatively high ratios could be identified in the aorta (2 out of 60, Fig. 2F) and vitelline artery (2 out of 44, Fig. 2G). We next evaluated intra-aortic clusters, a hallmark of EHT (Fig. 2H-N; supplementary material Fig. S2F-I) at later stages (E10.5-E11.5). Intra-aortic clusters are identified by CD41 (Itga2b) (Robin et al., 2011) and Kit (referred to here as c-kit) (Yokomizo and Dzierzak, 2010). Using both CD41 and c-kit as markers of hemogenic endothelium and/or EHT, we evaluated RUNX1 and SOX17 within CD41+ and CD41− populations, as well as within c-kit+ and c-kit− populations (Fig. 2H-K). Cells identified as c-kit+ or CD41+ consistently exhibited high levels of RUNX1 and low levels of SOX17 (Fig. 2J,K). When both positive and negative populations are evaluated, SOX17 and RUNX1 MFIs exhibit a negative correlation (Fig. 2L). Occasionally we observed a primarily non-nuclear localization of SOX17 in subsets of clusters cells (Fig. 2M), suggesting a possible role for this transcription factor in another cellular compartment. The nuclear ratios of RUNX1/SOX17 per individual cell in a cluster exhibited some variability, but a strong tendency towards ratios >1.0 (18 out of 19), consistent with hematopoietic identity (Fig. 2N). The ratios among endothelial cells near the cluster were notably lower (Fig. 2N), possibly signifying non-hemogenic endothelium.

Correlative microscopy reveals cellular topography of hemogenic endothelium

To examine the surface morphology of hemogenic endothelium, immunofluorescence was correlated with scanning electron microscopy (SEM) analysis. Images from both types of microscopic evaluation are combined via anatomical landmarks, with a resulting overlay of both immunofluorescence and SEM micrographs. Single cells of entire aortas can be evaluated for RUNX1 and SOX17 with corresponding cellular morphology at ultra-high resolution (Fig. 3; supplementary material Fig. S3). Cells within the hemogenic endothelial layer that exhibit nuclear RUNX1 immunofluorescence are noted to exhibit a range of...
morphological attributes; as compared with cells that exhibit high SOX17 levels and very low to non-detectable RUNX1 levels (Fig. 3A-D; supplementary material Fig. S3A-H). Overall, the correlative approach defines endothelial cells, with commensurate flat-like cell morphology and integration into the endothelial layer, as exhibiting high SOX17 and low RUNX1 levels (Fig. 3E,F).

Strikingly, endothelial cells that exhibit detectable RUNX1 levels demonstrate unique cellular morphology, with more oblong and rounded cell bodies and filopodia-like protrusions of the membrane (Fig. 3E,F; supplementary material Fig. S3I). Thus, the correlative technique allows visualization of aortic endothelium at single-cell resolution with corresponding quantification of immunofluorescence levels and high-resolution cell morphology.

EHT can be identified through correlative microscopy

In order to identify single hemogenic cells during all stages of EHT, we analyzed complete aortas via our correlative microscopy approach. Murine aortas at E10.5 and E11.5 were analyzed for SOX17 and RUNX1 immunofluorescence and cell surface morphology (Fig. 4; supplementary material Fig. S4), in addition to CD41 and c-kit immunofluorescence (supplementary material Fig. S4-A-G). Intra-aortic cluster cells are easily identifiable and exhibit high RUNX1/SOX17 ratios and membrane extensions/protrusions (Fig. 4A-E; supplementary material Fig. S4-A-E). We next analyzed single cells embedded within the endothelium. Most cells exhibit high SOX17 levels, but a few cells also exhibit detectable levels of RUNX1 (Fig. 4F,G, magenta and cyan numbers). Overall, our analysis reveals a population of cells with varied RUNX1/SOX17 ratios (Fig. 4H). Cells with little to no RUNX1 exhibit phenotypic endothelial morphology of elongated, flattened cell bodies with smoother cell surfaces (Fig. 4F,G, blue numbers). A higher ratio correlated with rounder morphology and directly correlated with the presence of membrane protrusions (Fig. 4E-G, cyan and pink numbers, Fig. 4I-L; supplementary material Fig. S4H). These protrusions are generally found within the RUNX1+ cell population (Fig. 4I-L). The data demonstrate that as a cell transitions through EHT (as defined by the RUNX1/SOX17 ratio), cell morphological changes occur in association with active changes to the membrane surface.
Conclusions

By employing the technique of correlative scanning electron microscopy, we have discovered novel cellular events that accompany EHT. Our data demonstrate that during the hemogenic window small perturbations in SOX17 levels are accompanied by increased levels of RUNX1 (which might precede overt morphological changes) and identify a population of hemogenic endothelium. Once RUNX1 levels are increased, with a corresponding decrease in nuclear SOX17, a transition towards hematopoietic fate occurs, as evidenced by rounded cell shape and co-expression of CD41 and/or c-kit (Fig. 4M; supplementary material Fig. S4). In addition, the correlative microscopy approach demonstrates previously uncharacterized changes in membrane dynamics. The significance of membrane protrusions throughout the EHT process is currently unknown. However, similar protrusion-like extensions are observed in immune activation and inflammation (Yamamoto et al., 2015). As inflammation is becoming a more appreciated regulator of HSC emergence (Espín-Palazón et al., 2014; He et al., 2015; Li et al., 2014; Sawamiphak et al., 2014), the observed changes could be due to activation of inflammatory pathways in EHT. Moreover, the observation in the human system that changes in RUNX1 and SOX17 protein levels mirror those seen in the murine system, strongly suggest that similar cellular mechanisms take place in human hemogenic endothelium. These findings and the novel approach will further help to define the changes associated with endothelial-to-hematopoietic conversion. In addition, we introduce a new method of single-cell analysis within tissue/organ and organismal context that is widely applicable to other developmental and cell biological questions.
MATERIALS AND METHODS

Tissue collection

Human tissues were collected in accordance with the regulation and approval of the Committee on Human Research at the University of California, San Francisco, from elective procedures with informed patient consent in strict compliance with legal and ethical regulations. The Carnegie classification system was used for staging and correlated to gestational/menstrual age (GA).

Animals

Animal protocols were conducted in accordance with University of California at San Francisco Laboratory Animal Research Committee guidelines. Timed pregnancies of wild-type C57Bl/6J animals were dated by vaginal plugs.

Tissue processing for fluorescent microscopy

Embryos were fixed in 2% paraformaldehyde solution overnight and frozen in Tissue-Tek OCT Compound (Sakura Finetek, 4583). Cryosections of 20-30 μm thickness were obtained (Thermo Scientific Micron, HM550). Slides were dried for 1 h at room temperature (RT), washed with PBST (0.5% Triton-X100) and incubated in blocking buffer (PBST, 5% donkey serum) for 1 h. Primary antibodies (for full list of antibodies please see supplementary material Table S1) were incubated at RT for 6 h in blocking buffer. Slides were washed, incubated with secondary antibody for 1 h, washed, stained with 2 μg/μl DAPI and mounted in Vectamount (Vector Laboratories, H-5501). Images were captured on a Leica SPE Confocal Microscope and/or Zeiss LSM 780 and compiled using ImageJ and Imaris 7.6 (Bitplane) software.

Tissue processing and correlative microscopy

Embryos were fixed as described above, washed in PBS and embedded in 4% low-melting-point agarose, sectioned on a vibratome (Leica VT 100P) at 100-300 μm. Samples were incubated with 1.0% Triton-X100 in PBS for 1 h, immunostained and imaged as described above. Following image

Fig. 4. Single-cell analysis of endothelial-to-hematopoietic transition. (A) E11.5 aorta. RUNX1 (magenta) and SOX17 in green. RUNX1+ single cells identified by red asterisks, smaller clusters by magenta arrowheads and a large intra-aortic cluster by red dashed outline. Single channels in black and white. (B,C) RUNX1 and SOX17 MFI levels and ratios corresponding to cells in outlined area in A. Red and orange arrows correspond to cells identified in D. n=25. (D) SEM image of outlined area in A. The red and orange arrows identify cells with corresponding antibodies in E-G. (E) SEM image of four round cells attached to the endothelium with corresponding high RUNX1 (magenta), low SOX17 (green) MFI levels (right graph). Each cell is numbered in magenta, signifying a high RUNX1/SOX17 ratio per legend. (F) SEM image of cells depicted by colored numbers; colors correspond to ratios per legend. High RUNX1 (magenta) and low-intermediate SOX17 (green) MFI levels of two cells (arrows in right graph) correspond to cells numbered 8 and 9 in magenta. (G) SEM of cells with low and intermediate ratios depicted by colored numbers. RUNX1 and SOX17 MFI levels in right graph; arrows denote two cells with intermediate ratios numbered in cyan (#13 and #17) in left SEM micrograph. Surface morphology does not distinguish cells #13 and #14, but immunofluorescence analysis reveals two nuclei with two different ratios. (H) Bar graph of RUNX1/ SOX17 ratios of all numbered cells depicted in E-G separated by dashed lines; colors denote magnitude of ratio per legend, x-axis represents the designated cell number. (I) Correlation of RUNX1/SOX17 ratios to number of protrusions per μm² surface, for cells depicted in E-G. Correlation coefficient r suggests a direct correlation of high ratios to more protrusions per cell surface area. P-value and n as shown. (J) Percentage of cells with protrusions at E10.5 and E11.5 in RUNX1high and SOX17high subpopulations of aortic endothelium. Protrusions can be found primarily in RUNX1high cells. Total number of cells analyzed per aorta at E10.5; RUNX1high (n=38), SOX17high (n=98). E11.5; RUNX1high (n=28), SOX17high (n=81). (K) SEM of cells with various ratios denoted by colored dots: high (magenta), intermediate (cyan) and low (blue). (L) Rounded cell with a high ratio (magenta dot), and ultra-high-resolution image (boxed area) of protrusions on the surface of the cell. (M) Schema of the endothelial-to-hematopoietic transition (EHT). EC, endothelial cell; HC, hematopoietic cell. (A,D,E,G-K,L) Scale bars as shown.
acquisition, samples were re-fixed in 0.1 M sodium cacodylate/1% glutaraldehyde, pH 7.5, for 1 h, washed in 0.1 M sodium cacodylate, then dehydrated in a series of EtOH (30, 50, 70, 90, 100%) and dried using a critical-point dryer, followed by 8 nm Ir labeling prior to image acquisition on a Zeiss Ultra 55 FE-SEM.

Single-cell analysis
For single-cell analysis images were acquired with optimal z-stack distance ranging from 0.5 to 1.0 μm per stack in 8-bit mode. Image files were analyzed using Imaris 7.6 (Bitplane) software. Each individual cell nucleus was volume-rendered based on fluorescence signal from DAPI, SOX17 or RUNX1, using a surface creation algorithm (Imaris 7.6, Bitplane) in order to generate a measurement per channel of fluorescence intensity. Mean fluorescence intensities (MFI) ranged from 0 to a max of 255. For cells with nuclear SOX17 immunofluorescence, MFIs were measured based on fluorescence intensities (MFI) via non-parametric Spearman correlation in GraphPad (Prism). Cells were scored as positive for calculation of percentages.

Image acquisition and image comparison
Owing to inherent variability between microscopes, staining protocols and developmental stages of the tissue, image files obtained from separate microscopes Zeiss LSM 780 and Leica SPE did not undergo cross-comparative analyses. Only single cells within a single generated image file were compared with each other, but not between image files. Comparisons were measured via MFI of RUNX1 and SOX17 MFI via non-parametric Spearman correlation in GraphPad (Prism). Cells visualized having protrusions uniformly covering >10% of their surface area were scored as positive for calculation of percentages.
